NANOSAFE Conference

Grenoble, November 5-9 2018

maîtriser le risque |  
pour un développement durable

# Context

1. INERIS operates since end of 2014 a Nanosafety platform dedicated to the study of physical hazards of nanopowders
2. INERIS research program dedicated to:
  1. Acquiring general knowledge on fire and explosion hazards of ENM
  2. Adapting testing protocols to the specific behavior of ENM
  3. Establish good safety practices for handling hazardous ENM
  4. Use test results in safety studies (ATEX)
3. Collaboration with ISSeP (NANOGRRA project) around the characterization of fire and explosion hazards associated with nanomaterial (see. E. Bouhoule's (ISSep) presentation)
  1. Intercomparison of test results for CNT, Al

# Fire and explosion hazard characterization

Explosion violence (Kst, Pmax) : 20 L sphere : ISSeP and INERIS

Minimum Ignition Energy : Mike 3 apparatus : INERIS

Minimum Ignition Temperature of a 5 mm Layer : Hot plate : INERIS

Fire propagation : VDI protocol : INERIS

Material tested : nanometric aluminum powder 40-60 nm

Sold as partially passivated => should not present pyrophoric behavior

Aluminium powder, 99.9%			
NM-0039-UP	[7429-90-5]	Al	MW 26.98
APS: 40-60 nm		5 g	49.00 €
SSA: 20-48 m <sup>2</sup> /g		10 g	79.00 €
PM: spherical		25 g	139.00 €
Appearance: black powder		50 g	229.00 €
		100 g	379.00 €
	Danger, <b>UN1396; 4.3; PG II</b>		
Packaging: Partially passivated powder in PE bottle under Argon			

Substance is identified as flammable and producing flammable gas when in contact with water (class 4.3)

# Fire and explosion Nanosafety Lab

S-NANO Platform at INERIS, Verneuil-en-Halatte, France

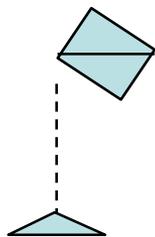

# Local context at beginning of the study

During preparation of samples for ecotoxicity tests at ISSeP, the powder ignited spontaneously => Fear of pyrophoric properties

=> Need to characterize the pyrophoric behavior and adapt test protocol for safety

=> Handling in glove box under Argon (below 3% O<sub>2</sub>) (INERIS) to prepare small size samples

=> Pyrophoric test needed to assess the risks during preparation of other tests

UN N2 test : drop the powder and see if it ignites within 5 minutes

=> Negative

Is this test always suitable for assessing the hazard of spontaneous ignition ?

What was the ignition mechanism involved ?

# Other preliminary testing

Self heating (5 mm layer, with continuous heating ramp up to 436°C (plate)).

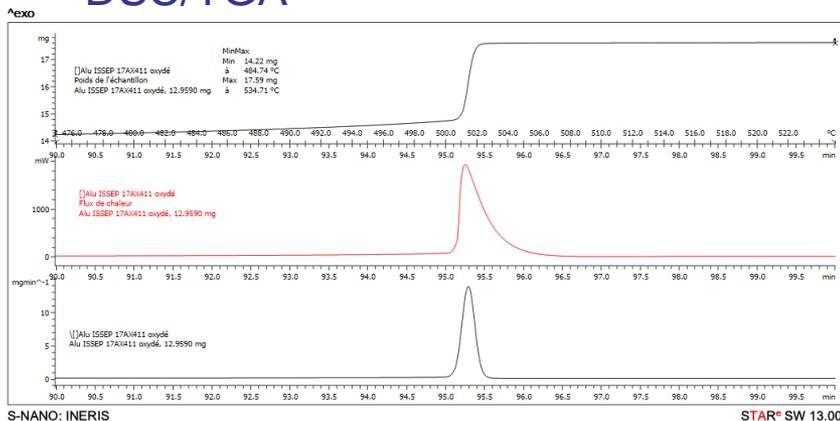

No ignition

(Low energy) Electrostatic discharge layer ignition

No ignition  
But no way to measure how much energy was actually delivered

## DSC/TGA

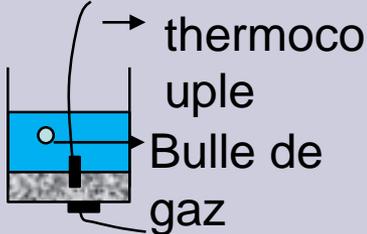

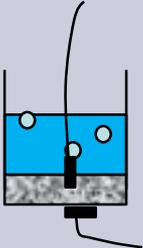

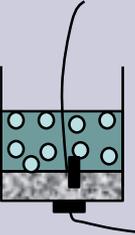

Onset 508°C (test 1)  
50% of Al as  $\text{Al}_2\text{O}_3$  (6 nm layer for a 50 nm particle)

Onset 501°C (test 2)  
43% of Al as  $\text{Al}_2\text{O}_3$  (5 nm layer for a 50 nm particle)

Based on hypothesis of 100% conversion to  $\text{Al}_2\text{O}_3$

# Reaction to water

Time	Day 1	Day 2, 12 h	Day 2, 16h
	 <p>thermocouple Bulle de gaz</p>		
Temperature evolution	+ 0,3 °C	*	T <sub>max</sub> = 27 °C
Gas emission	Weak	Moderate	Fast
Appearance of the water solution	clear	clear	troubled

# Minimum ignition energy

## Two stage ignition for high concentration

Spark

Primary ignition

Secondary ignition  
(air pulse)

Cause : incomplete combustion in quiet air (primary ignition) due to lack of oxygen

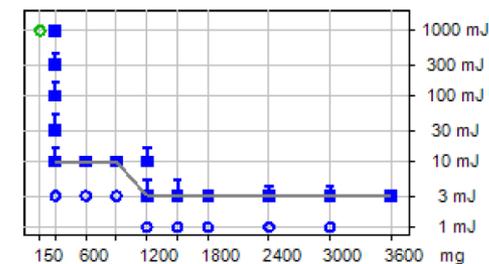

The air pulse brings the fresh oxygen to burn

1g of Al requires 3 L of air for complete combustion

The tube has a volume of 1 L

Result with inductance  $L = 1 \text{ mH}$

$1 \text{ mJ} < \text{MIE} < 3 \text{ mJ} / E_s = 1,6 \text{ mJ}$

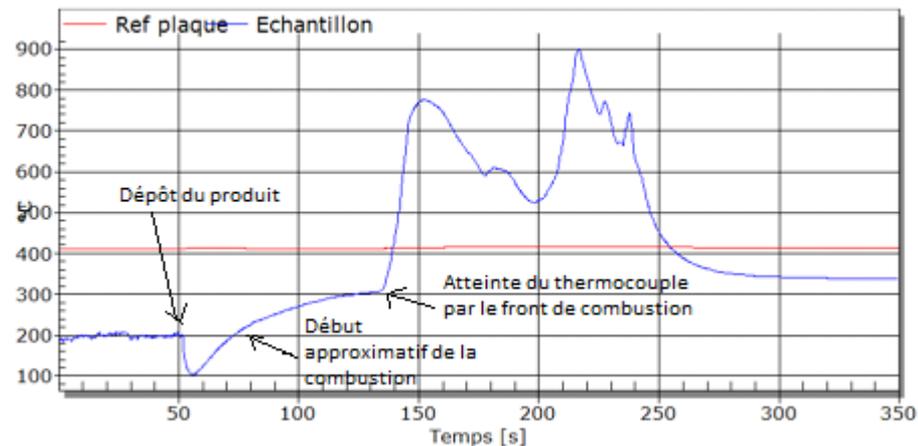

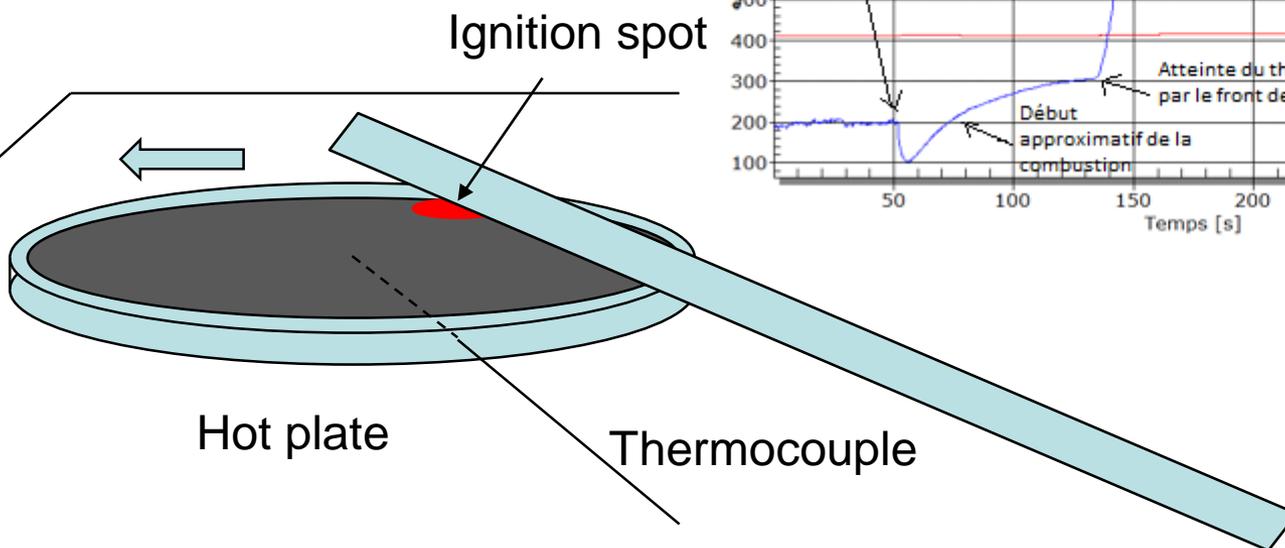

# Ignition by sparks (burning particles)

# Ignition by friction

Ignition occurred during layering of the dust at contact point between dust and retention circle

# Two combustion regimes

Initially cold

Initially hot ( $\sim 300^{\circ}\text{C}$ )

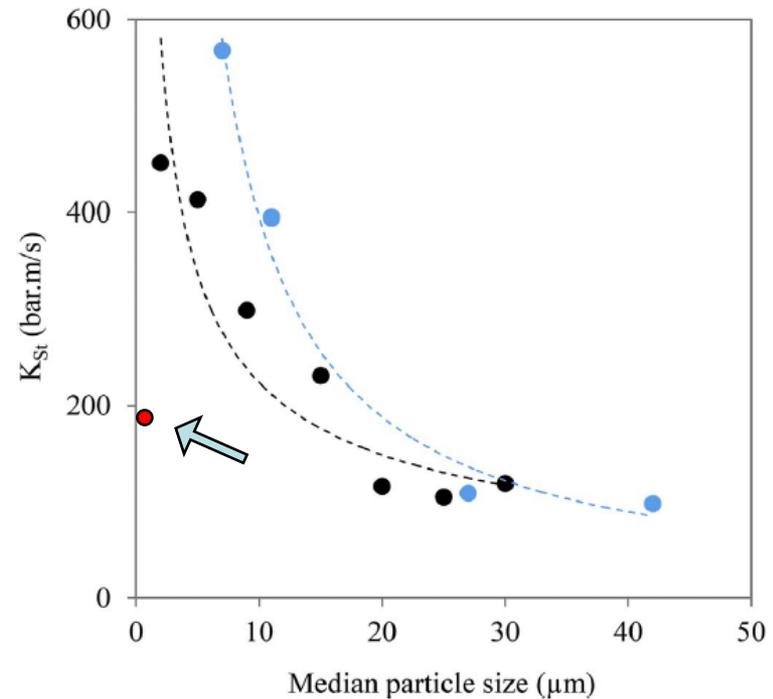

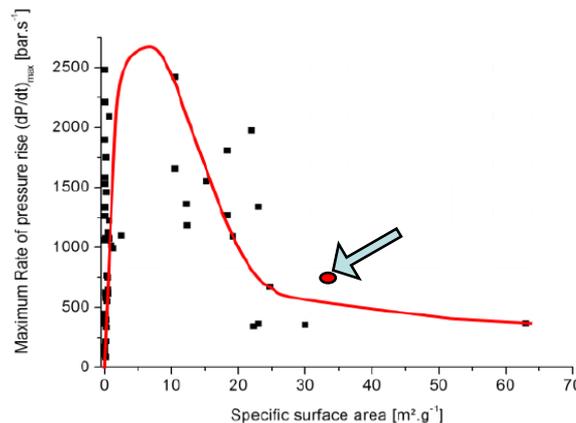

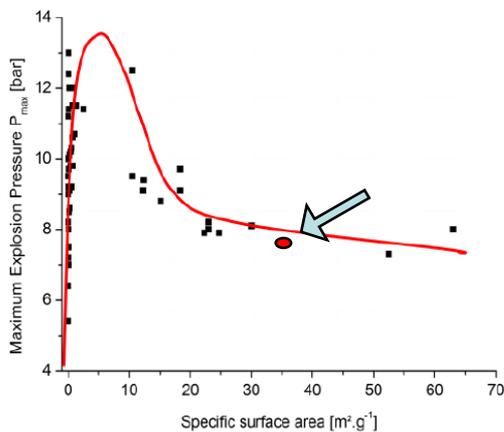

# Explosion violence

Essai à 10 kJ	
$P_{\max}$ (bar)	7,9
$dP/dt$ (bar/s)	701
$k_{\max}$ (m.bar/s)	190

Explosion violence seems low if compared to available data on micrometric aluminum powder

But in good agreement with (Bouillard and Vignes, 2010) and subsequent more recent works

# On pyrophoric behavior

Two interpretation of the pyrophoric behavior :

## A. Single particle pyrophoricity.

The heat balance at particle level governs its reactivity.

$$\begin{cases} \frac{dE_{ox}}{dt} = \frac{d(m_{ox} C_{p_{ox}} T_{ox})}{dt} = Q_{prod} - Q_{ext} - Q_{metal} \\ \frac{dE_{metal}}{dt} = \frac{d(m_{metal} C_{p_{metal}} T_{metal})}{dt} = Q_{metal} \end{cases}$$

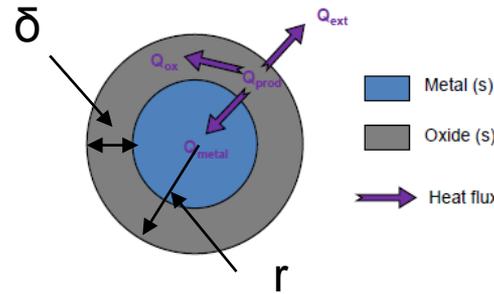

Figure 35 : Heat balance performed on a pyrophoric particle

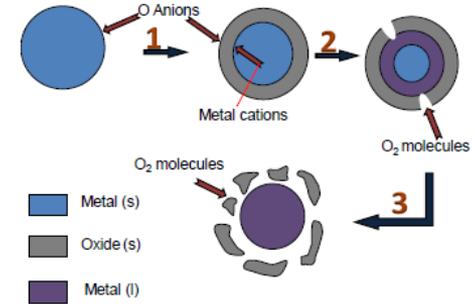

Figure 36 : Sketch describing the steps in pyrophoricity phenomenon

Based on the Glassmann theory a limit oxyde/radius ratio was assessed by for Aluminum beyond which it could become pyrophoric

$$\delta/r = 0,18$$

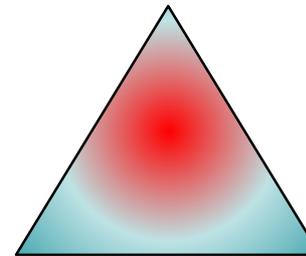

To be compared with the **0,2** and **0,24  $\delta/r$  ratio** measured by DSC/TGA

Source : A. Vignes, Final report of Eu Project MARINA

## B. Low volume/temperature self heating

The heat balance in the pile governs the heat rise and global kinetics of the reaction as described by the Franck-Kamenetskii model.

Still needs to be fully explored for this nanometric Al  
Although layer self ignition temperature have shown no specific self-heating behavior

$$\left( \frac{d^2T}{dx^2} + \frac{j}{x} \frac{dT}{dx} \right) = - \frac{Q \cdot \rho \cdot A \cdot e^{\left(\frac{-E}{RT}\right)}}{\lambda}$$

# Conclusion

Experiments carried out in partnership with ISSep on nanometric Aluminum.

Good agreement with previous experimental studies for :

- Minimal ignition energy
- Explosion violence

Cause of spontaneous ignition still not clear

- Pyrophoricity due to insufficient  $\text{Al}_2\text{O}_3$  layer thickness ?
- Self-heating behavior ?
- Sensitivity to friction : still needs to be confirmed by dedicated tests ?

Different combustion behaviors depending on the fate of the oxide layer ?

Adequate characterization of the ignition mechanism and efficiency of the passivation is an issue for industrial safety when handling such powders
